

WHEN TRUST MATTERS

Physics-Informed Data-Driven Approaches to State of Health Prediction of Maritime Battery Systems

PHM 2024,
Nashville, Tennessee, USA

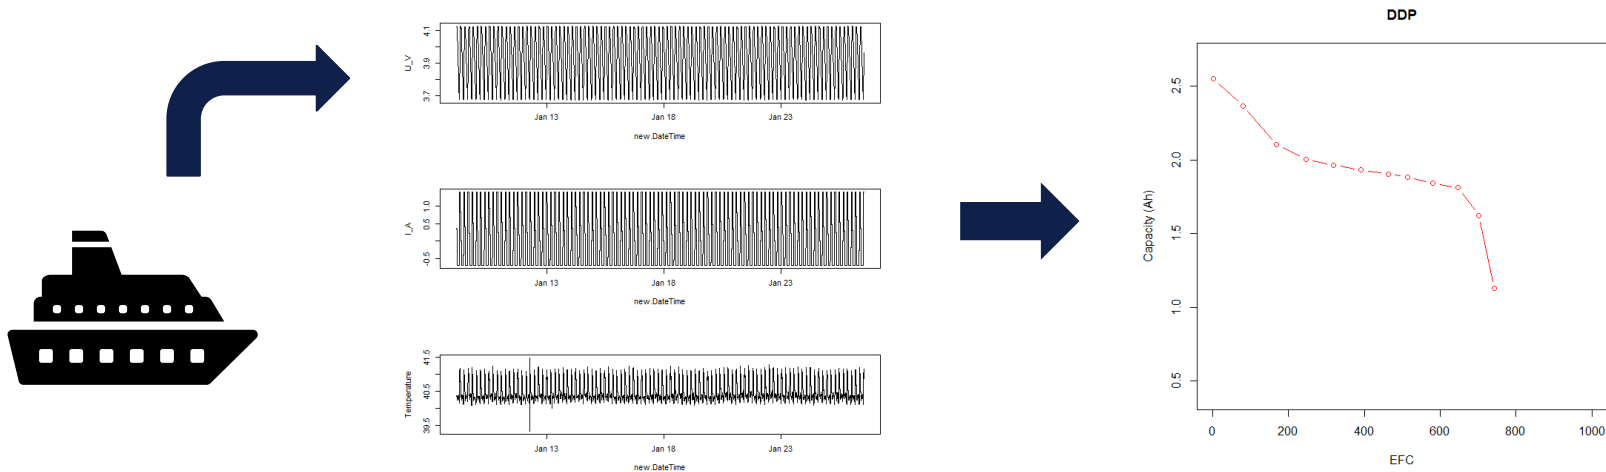

A. Bakdi, M. Bruch, Q. Liang, **E. Vanem**

13 November 2024

Introduction and motivation

- Available energy information is important for the safety of electric ships → Need to monitor SoH
- SoH estimated by BMS, but difficult to assure accuracy
- Class requirement that SoH from BMS should be verified by an independent method
 - Typically done by an annual capacity test
 - Annual capacity test is time consuming and costly → want to go for data-driven verification of SoH

Background

- Previous attempts with purely data-driven methods failed to meet expectations*

Cumulative models:

- Estimate contribution to degradation from each cycle and add up to get current SoH

$$SOH(c_n) = 100 - \sum_{i=1}^n \Delta SOH(c_i)$$

- Computationally expensive – do not scale well to large battery systems
- Requires full operating history of the batteries

Semi-supervised learning

- Train models on pseudo-capacity extracted from operational data; but do only have SoH from annual tests
- Assume constant SoH in a time-window around annual tests and look for “similar” cycles
- Build a statistical model on newly labelled data
- Dependent on previous vessels having relevant data; experienced similar conditions and degradation

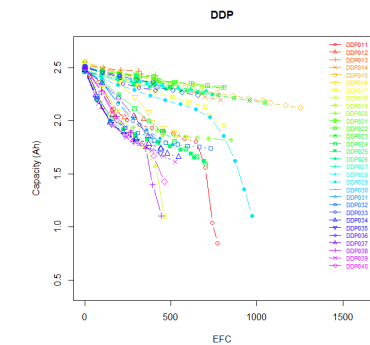

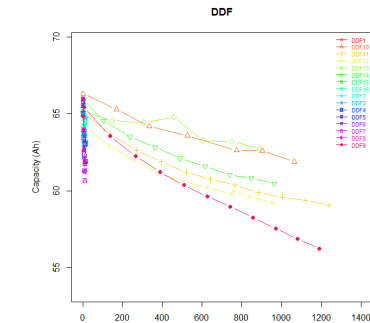

Snapshot methods

- Based on extracting features from charge/discharge curves
- Establish models for the relationship between these features and SoH
- Results OK for about 40% of the cells
- Possibly because lack of representative training data

Available data sources

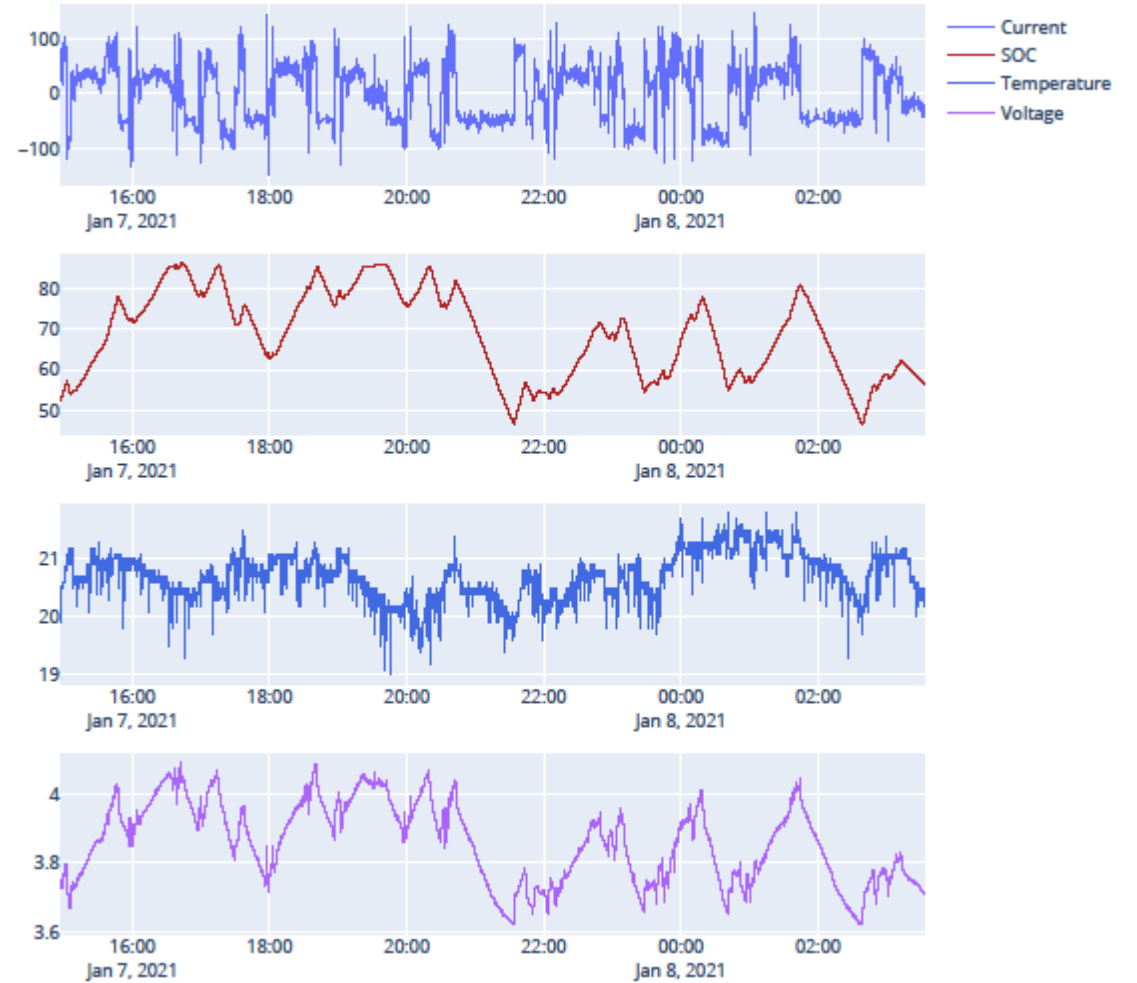

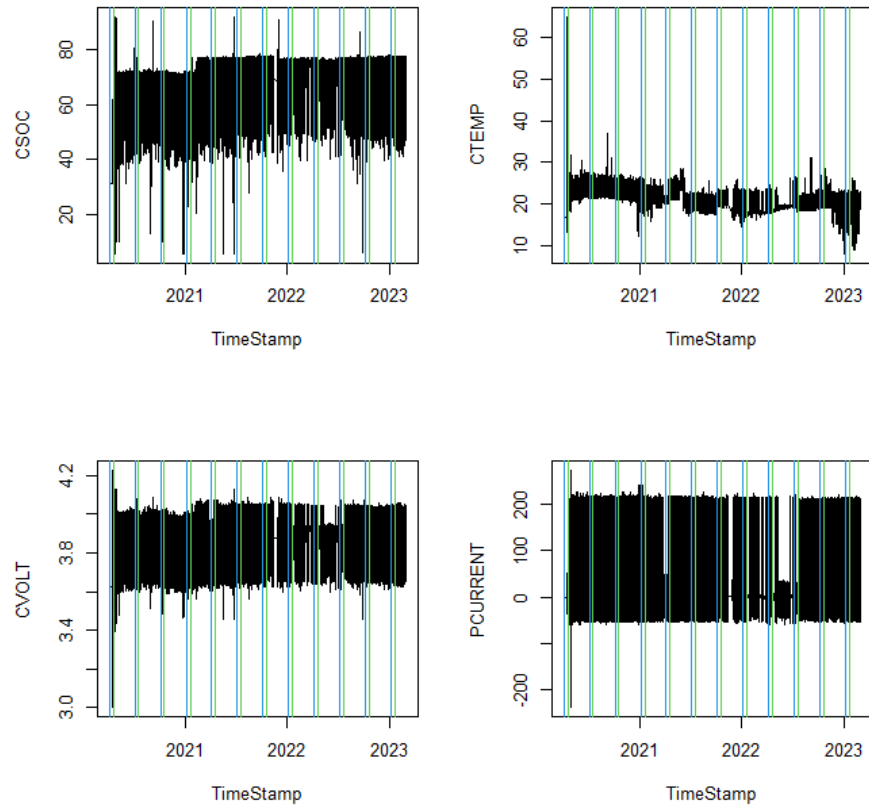

- Battery cells have been cycled within the project to obtain lab data
 - Fraunhofer and Corvus labs; DDE, DDP and DDF cells
 - Time-series of current, voltage and temperature with regular check-ups
- Operational data have been collected from several vessels
 - Vessels A – F; similar cells as DDF (pouch cells)
 - Time-series of current, voltage, temperature and SOC + annual test results
 - Ferries and offshore vessels: all-electric and hybrid
- Some publicly available dataset
- One problem is that different chemistries and cell types have very different degradation.
 - Need training data from the *same cell types* as the ones to monitor with data-driven approaches

Example of operational data from ships in service

Field data Vessel_E_Array1_Pack1_Module1_Cell1

Data-driven SoH estimation

- Earlier attempts on pure data-driven methods did not meet expectations
 - Accuracy and robustness
 - Computational cost and scalability to very large battery systems
 - Data requirements; full operational history and need for high-quality representative training data
 - Accounting for all perceivable operating conditions
 - Different approaches were encouraging but not quite good enough
- Concluded that data alone is not enough!
 - Purely data-driven models not sufficient, need to utilize physical insight
 - Explore physics-informed data-driven models, combining simple physical principles with sensor data

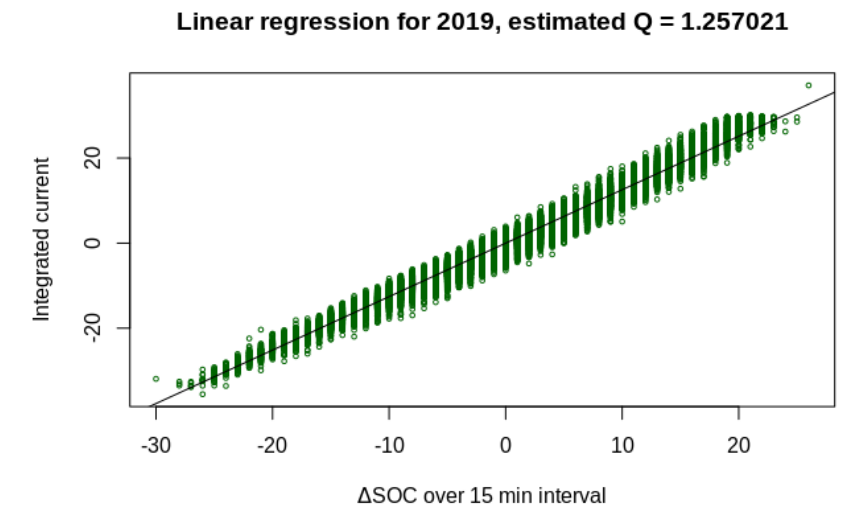

Data-driven SoH estimation utilizing physical principles

- Exploits fundamental relationship between integrated current and change in SoC
 - Model for degradation without the need for training data
 - Capacity, Q , is regression coefficient between integrated current and change in SOC

$$\int_{t_1}^{t_2} \eta I(\tau) d\tau = Q(\text{SoC}(t_2) - \text{SoC}(t_1)) \rightarrow Y = QX$$

- May be solved by OLS: $Y = QX + \varepsilon$
- Or by TLS, accounting for measurement error in both Y and X to remove attenuation bias: $Y + \Delta Y = Q(X + \Delta X)$

Simple linear model based on Coulomb counting

- Performs well on lab-data

Difference in SOC vs. integrated current
Partial charge cycles
DDE055

Estimated capacity from partial curves
DDE056

C-rate charge:0.2
C-rate discharge:0.2

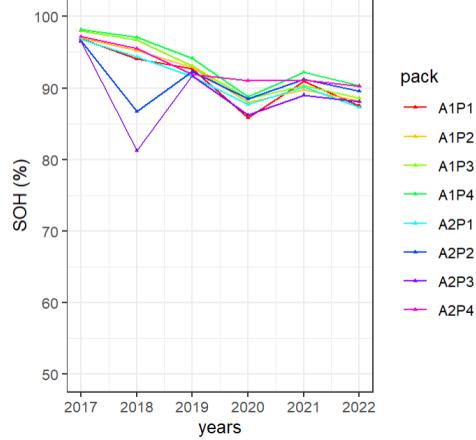

x: estimated from n last cycles before checkup

- More challenging on operational data
 - More noise; more variable conditions

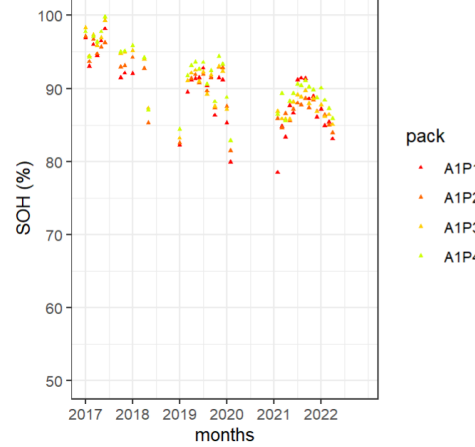

- Variable results

- Initial attempts did not appropriately account for changes in loading conditions

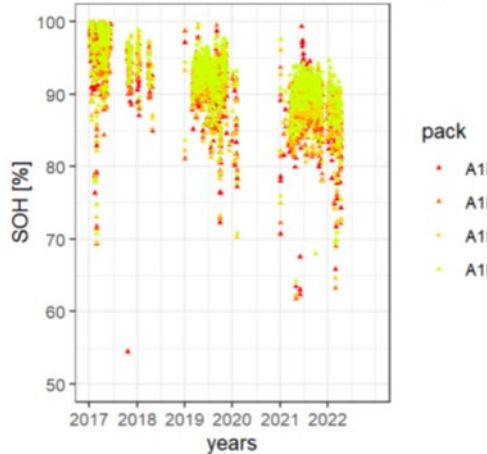

Yearly SOH estimates (charge cycles)

Monthly SOH estimates (all cycles)

Daily SOH estimates (all cycles)

Ensembles of simple linear models

- Use an ensemble of simple linear models to account for variable operating conditions
 - Apply the model on various subsets of the data; filtering and pre-processing
 - Apply the model to segments of the charge and discharge curves between specified voltage ranges
 - Individual estimates from pure charging and discharging; and both
 - Final estimate based on average of individual estimates; normal and weighted average
- Four voltage ranges specified (between cut-off voltages of 3.0 and 4.2 V):
 - 3.65 – 3.7 V
 - 3.7 – 3.8 V
 - 3.8 – 3.9 V
 - 3.9 – 4.0 V
- This yields 8 point-estimates for each selected time period
- Use 14-days snapshots 3 months apart

Ensembles of simple linear models

Segments of charge/discharge curves

Vessel_E_Array1_Pack1_Module1_Cell1: 2022-04-06 - 2022-04-19
Discharge: 3.8 - 3.7 V

Charge: 3.7 - 3.8 V

Extracted data and fitted linear models

Vessel_E_Array1_Pack1_Module1_Cell1
voltage range: 3.8 - 3.7

Ensemble of simple linear models – capacity prediction examples (vessel A)

Vessel_A_Array1_Pack1_Module1_Cell1 - Predicted capacity with confidence intervals

Vessel_A_Array1_Pack1_Module5_Cell4 - Predicted capacity with confidence intervals

Vessel_A_Array1_Pack1_Module7_Cell8 - Predicted capacity with confidence intervals

Ensemble of simple linear models – capacity prediction examples (vessel C)

Vessel_C_Array1_Pack1_Module1_Cell1 - Predicted capacity with confidence intervals

Vessel_C_Array2_Pack4_Module8_Cell12 - Predicted capacity with confidence intervals

Vessel_C_Array2_Pack8_Module4_Cell1 - Predicted capacity with confidence intervals

Ensemble of simple linear models – capacity prediction examples (vessel E)

Vessel_E_Array1_Pack5_Module8_Cell9 - Predicted capacity with confidence intervals

Vessel_E_Array2_Pack3_Module1_Cell1 - Predicted capacity with confidence intervals

Vessel_E_Array2_Pack9_Module9_Cell9 - Predicted capacity with confidence intervals

Ensemble of simple linear models

- Results generally better for Vessels C and E compared to A
 - Vessel A is hybrid; vessels C and E are fully electric
- One problem with the simple linear model is the reliance on SoC
 - SoC is a derived quantity not directly measured – it may not be accurate enough
 - More accurate algorithms for SoC calculation can improve capacity estimation
- A possible remedy for this is to rather use open circuit voltage (OCV)
 - Need to obtain an estimate of the OCV from the data

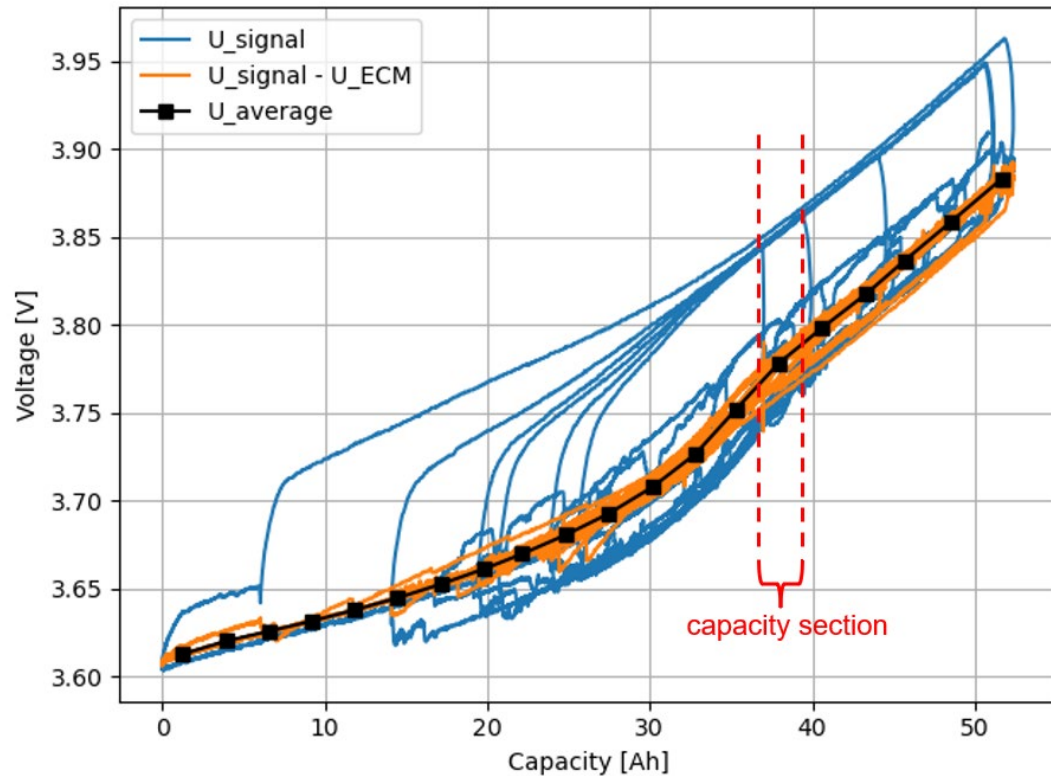

Methods based on open circuit voltage (OCV)

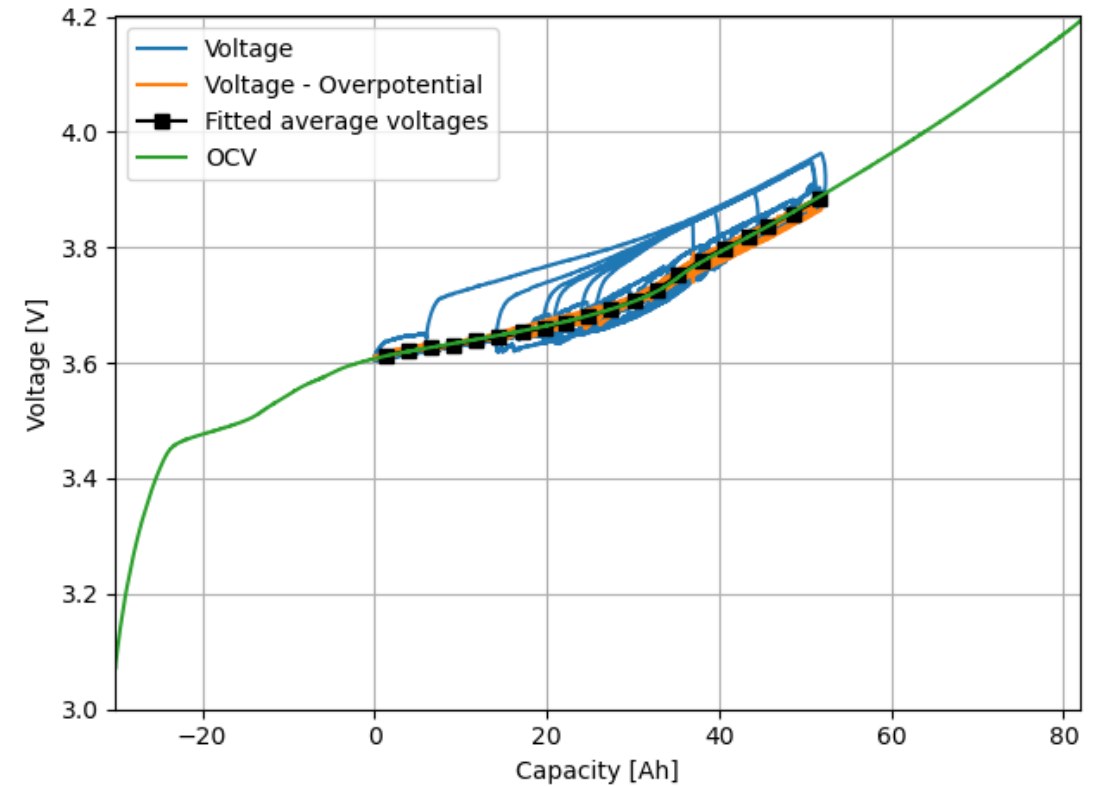

- This approach utilizes the correlation between capacity and open circuit voltage
 - OCV is increasing with SoC, but the relationship is not linear
 - There is also a small influence of temperature and SoH
 - The challenge is to estimate OCV when the cell is not at rest
- An equivalent circuit model (ECM) can be used to describe the overpotential
 - OCV can be obtained by subtracting the overpotential from measured voltage
 - OCV can then be related to the capacity at 100% SoC using a **known** OCV-SoC curve
- The only necessary prior knowledge is the OCV-SoC curve
 - May be obtained from initial laboratory testing
- In this study, an ECM with a serial resistance and 3 RC elements is assumed
 - Parameters are estimated by least squares to minimize voltage fluctuations within a narrow capacity range

Methods based on open circuit voltage (OCV)

Subtracting overpotential from measured voltage

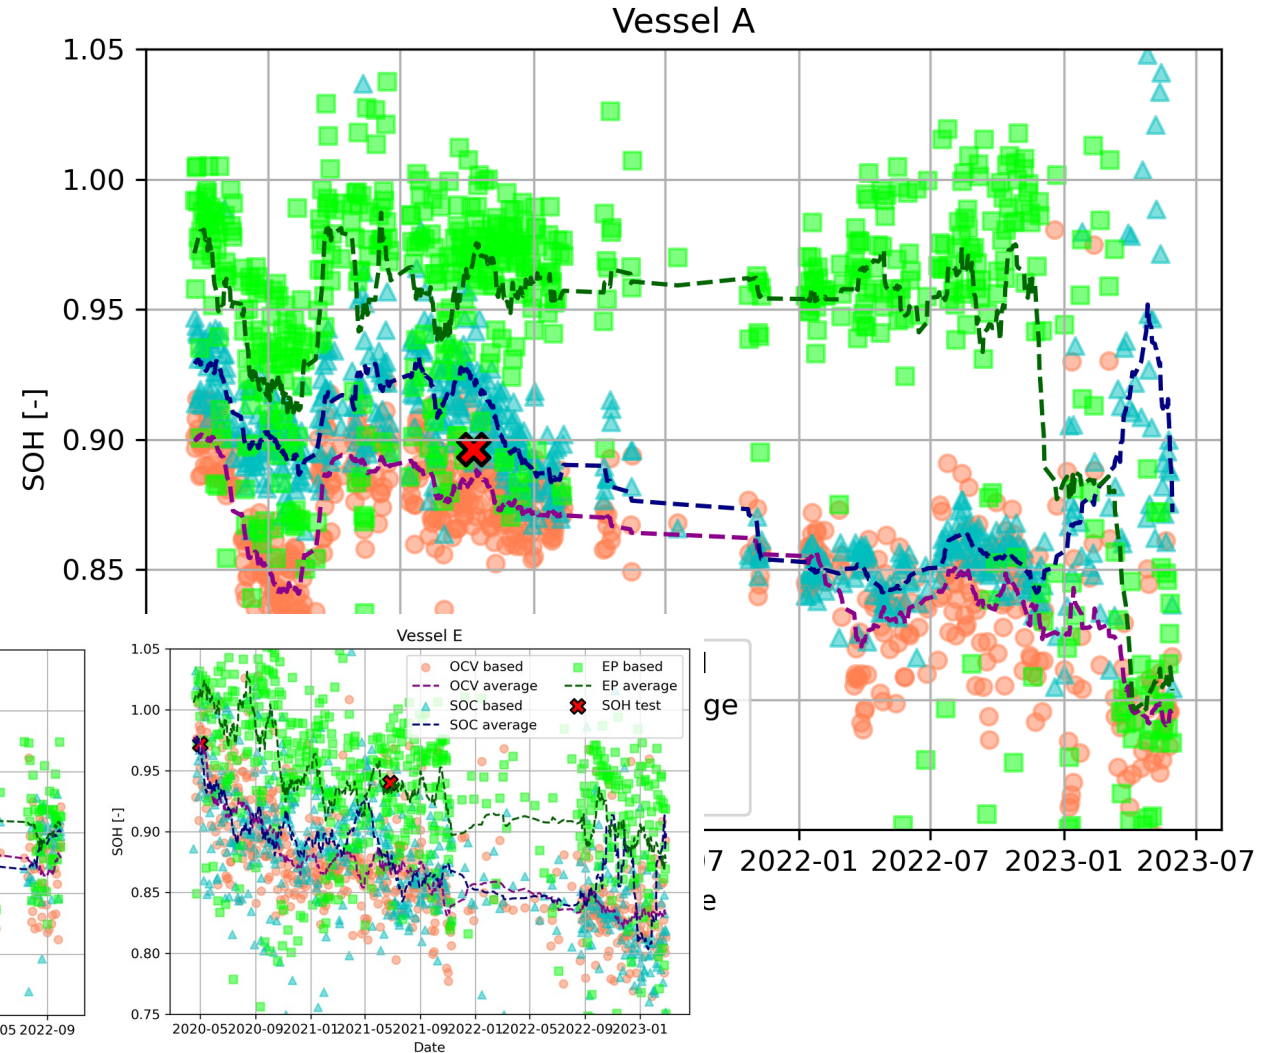

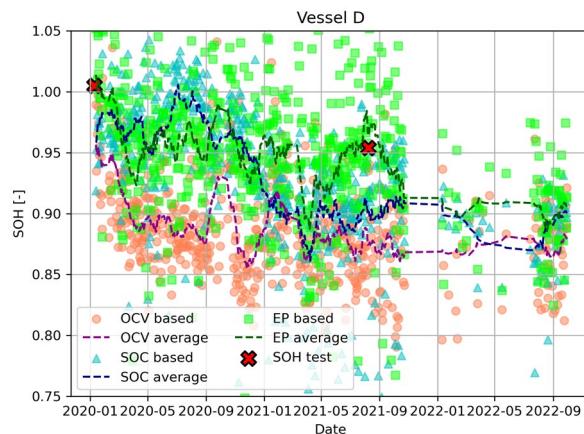

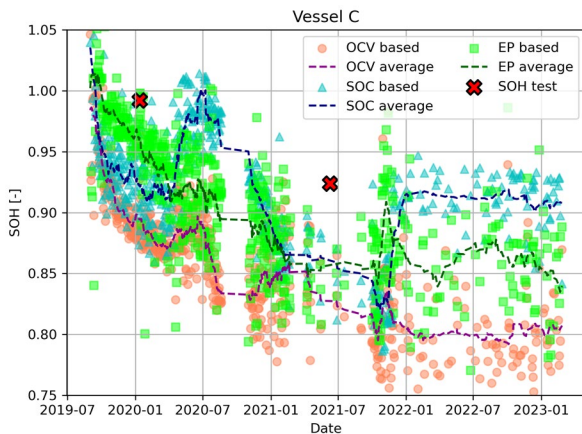

Fitting to known OCV curve

Methods based on open circuit voltage (OCV)

- Results are found to have questionable accuracy and low precision
- Voltage signal might not provide sufficient significant information
- Large variability indicates overfitting
 - Might be improved by regularization

Methods based on equivalent circuit models (ECM) and extensive characterisation tests

- The previous method is extended with a more complicated ECM model and extensive characteristics testing to account for variations in current and temperature
- ECM with serial resistance, 2 RC elements and a thermal and a hysteresis model

- ECM defines a set of five states: $x = \begin{bmatrix} SoC \\ U_1 \\ U_2 \\ h \\ T \end{bmatrix}$. Cell voltage and overpotential given by $V = OCV(x) + OP$
 $OP = IR_0(x) + U_1 + U_2$

Cell states and state change

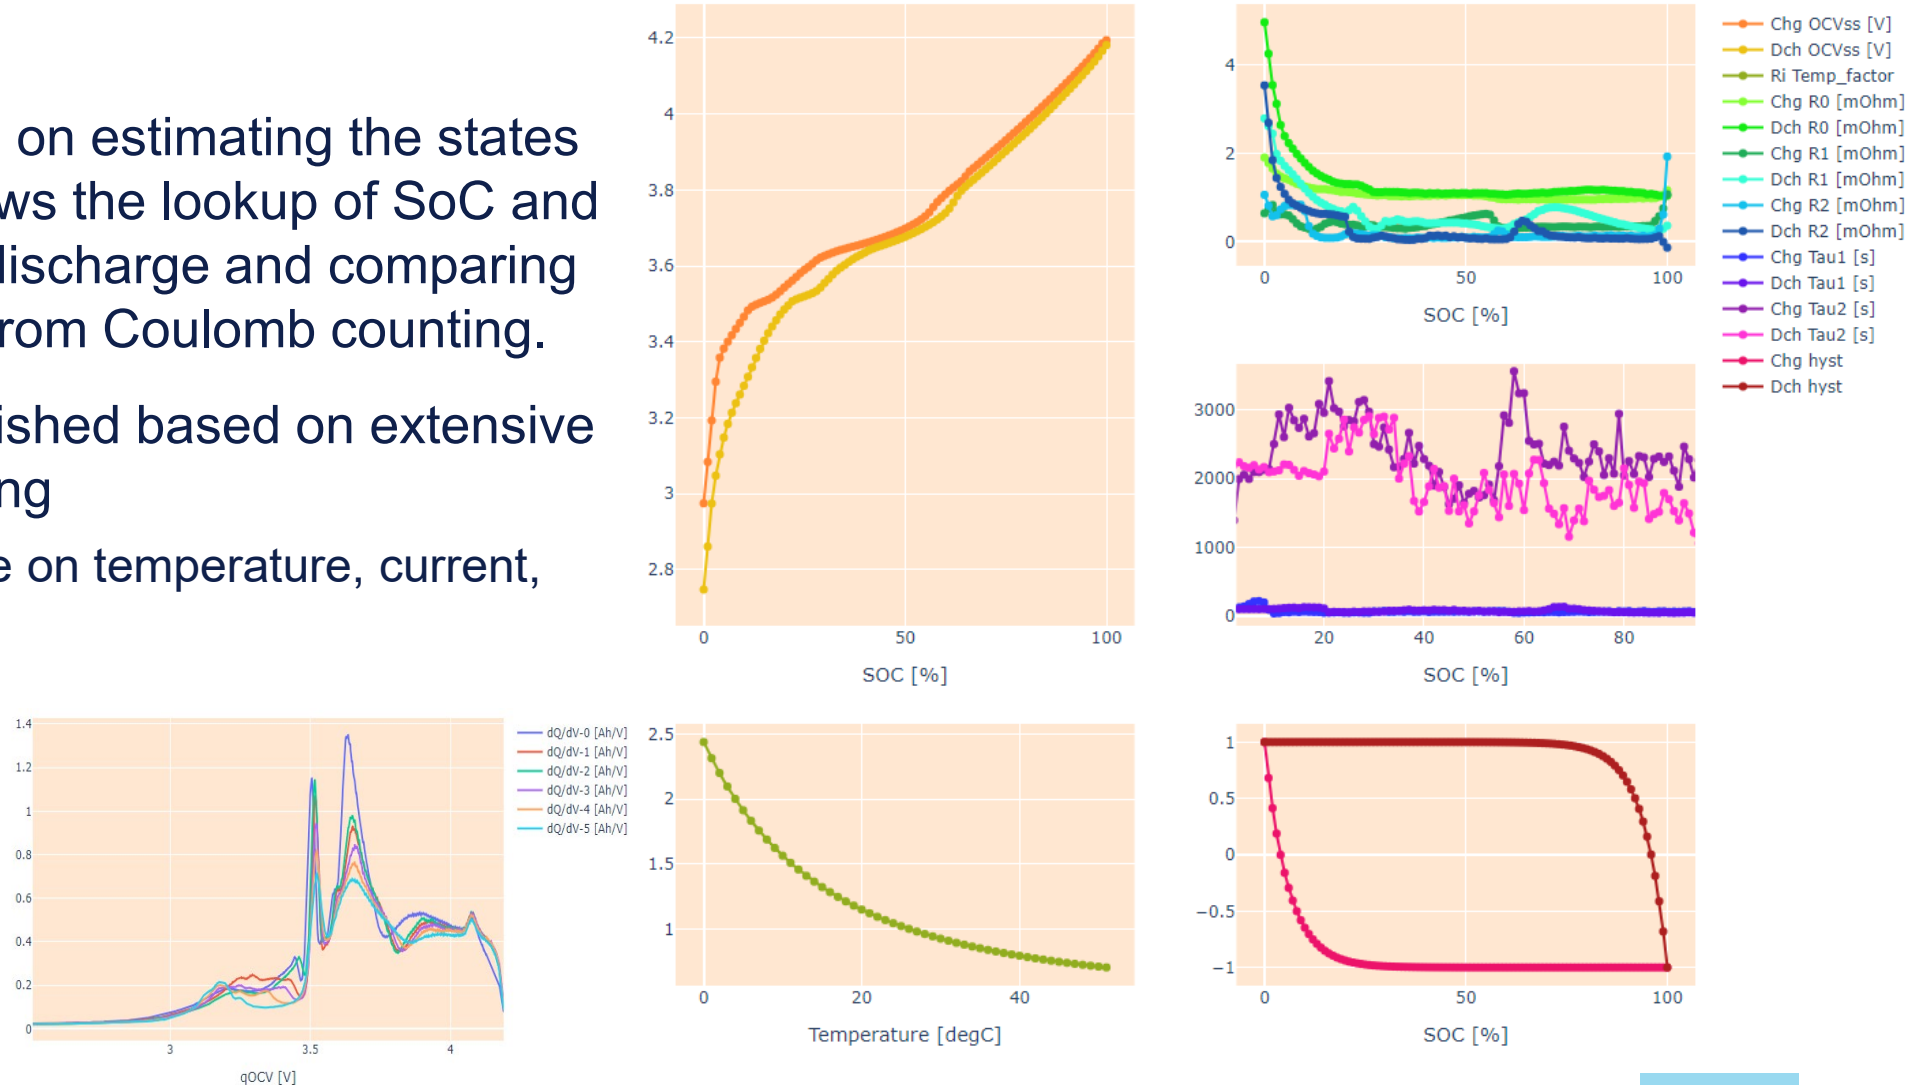

- Each of the circuit elements depend on cell states and conditions
 - E.g. OCV and internal resistance depend on SoC, SoH, T and h

- The state change according to a set of differential equations: $\frac{\partial x}{\partial t} = \begin{bmatrix} \eta \frac{I}{SoH \times C_{nom}} \\ \frac{IR_1(x) - U_1}{\tau_1(x)} \\ \frac{IR_2(x) - U_2}{\tau_2(x)} \\ f_h(x, I) \\ \alpha R_0(x) I^2 - \beta(T - T_\alpha) \end{bmatrix}$
- Integrating between two SoC values gives: $SoH \times C_{nom} \times (SoC_2 - SoC_1) = \eta \int_{t_1}^{t_2} I dt$

Method overview

- The method is based on estimating the states OP and h, which allows the lookup of SoC and calculating depth of discharge and comparing with actual capacity from Coulomb counting.
- Lookup tables established based on extensive characterization testing
 - Establish dependence on temperature, current, hysteresis, etc...

CellBlock ECM data

Verification on operational field data

- Verification and validation based on
 - Calculate SoH from operational data for selected modules
 - Send modules to the lab and perform lab capacity check-up
 - Compare SoH calculated from operational data with SoH from laboratory check-up
 - Note: there may be some delay between operational calculation and lab; calendar aging
- Module SoH is assumed to be the lowest cell SoH within the module
- In total 6 validation scenarios reported in the paper
 - Scenario 1: hybrid ferry with 79.7% SoH from lab and 79.7% SoH from field measurements
 - Scenario 2: hybrid bulk carrier with 93.25% SoH from lab and 93.50% from field data
 - Scenario 3: same vessel as Sc.2; lab = 92.38% and field = 92.85%
 - Scenario 4: Shore station. SoH difference in the range of 1 – 2 %
 - Scenario 5: fully electric ferry. Lab = 83.8%; field = 85.2%. (1 year lag; defect cell)
 - Scenario 6: Shore station. Lab = 73.7%; field = 76.1% (1 year lag; DoD about 40%)

Discussion

- Attempts with purely data-driven models for capacity estimation failed on actual operational data
 - Although they can perform well on laboratory data
- A simple linear model based on Coulomb counting is attractive; it does not need training data
 - Not accurate enough, probably due to reliance on SoC
 - Ensemble methods can improve results, but dependence on SoC remains
- A modified method relating capacity to OCV was developed, utilizing a simple ECM
 - Initial results highly variable, although average predictions are somewhat reasonable
- Supplementing this approach with comprehensive lookup tables from characterization tests to account for temperature, hysteresis and current effects yields reasonable results
 - Still requires “deep enough” cycles to have been experienced in the operational data
 - This method has already been used in actual verification of capacity for electric ships in operation, as announced in a recent [press release](#)

Summary and conclusions

- Purely data-driven models for capacity and SoH estimation for operational conditions is challenging
- Carefully constructed physics-informed, data-driven models may improve this by utilizing fundamental physical knowledge
 - Final model is based on Coulomb counting, ECM, extensive characterization tests and snapshots of sensor data collected during normal operation
 - But requires some “relatively deep” charge and discharge cycles
- Further validation is recommended – particularly for batteries approaching their end of life
 - And for other battery chemistries
- Facilitates continuous verification of SoH without disrupting normal operations
 - Considerable benefit for operators of electric ships
 - Can relax strict requirements of test protocols for annual tests
